A WEB IMPLEMENTATION OF A GENERALIZED NEP

David Batard, Sandra María Gómez and Abraham Gutiérrez

Abstract: The Networks of Evolutionary Processors (NEPs) are computing mechanisms directly inspired from the behavior of cell populations more specifically the point mutations in DNA strands. These mechanisms are been used for solving NP-complete problems by means of a parallel computation postulation. This paper describes an implementation of the basic model of NEP using Web technologies and includes the possibility of designing some of the most common variants of it by means the use of the web page design which eases the configuration of a given problem. It is a system intended to be used in a multicore processor in order to benefit from the multi thread use.

Introduction

Networks of Evolutionary Processors (NEP) are a rather new computing mechanism directly inspired from the behavior of cell populations. Every cell is described by a set of words, evolving by mutations, which are represented by operations on these words, resembling the manner carried out by DNA strings [Păun, 1998]. At the end of the process, only the cells with correct strings will survive. The main potential in this model is the simultaneous way it develops for which a basic architecture for parallel and distributed computing is required consisting on several processors, each of them placed in a node of a virtual complete graph, which are able to handle data associated with the respective node. Each node processor acts on the local data in accordance with some predefined rules. Local data is then sent through the network according to well-defined protocols. Only data which is able to pass a filtering process can be communicated. This filtering process may be required to satisfy some conditions imposed by the sending processor, by the receiving processor, or by both of them. All the nodes simultaneously send their data and the receiving nodes also simultaneously handle all the arriving messages, according to specific strategies. In addition, the data in the nodes is organized in the form of large multiset of words where each word could appear in an arbitrarily large number of copies and all the copies are processed in parallel so that every possible action takes place.

This basic model has evolved to others which extend not only the definition but the applications. In this case we consider the hybrid networks of evolutionary processors (HNEP) where the rules in every processor could be applied differently opposed to the basic model as described in [Martin-Vide, 2003]. Also other variants can be considered as they all share the same general characteristics.

In this paper we describe the initial work of implementation of a general NEP which can be thought to represent the most common variations of the basic model, considering the concurrent way it was conceived to perform and having a graphic user interface for an easier way of defining it and getting the outcomes.
Basic concepts

A network of evolutionary processors of size $n$ is a construct:

$$\Gamma = (\mathcal{V}, N_1, N_2, \ldots, N_n, G)$$

where $\mathcal{V}$ is an alphabet of symbols and for each $1 \leq i \leq n$, $N_i = (M_i, A_i, PI_i, PO_i, FO_i)$ is the $i$-th evolutionary node processor of the network.

The parameters of every processor are:

$M_i$ is a finite set of evolution rules of one of the following forms only:

- $a \rightarrow b \quad a, b \in \mathcal{V}$ (substitution rules);
- $a \rightarrow \varepsilon \quad a \in \mathcal{V}$ (deletion rules);
- $\varepsilon \rightarrow a \quad a \in \mathcal{V}$ (insertion rules).

In this case for the hybrid NEP we are considering each deletion node or insertion node having its own working mode (performs the operation at any position, in the left-hand end, or in the right-hand end of the word) and different nodes are allowed to use different ways of filtering. Thus, the same network may have nodes where the deletion operation can be performed at arbitrary position and nodes where the deletion can be done only at the right-hand end of the word.

$A_i$ is a finite set of strings over $\mathcal{V}$. The set $A_i$ is the set of initial strings in the $i$-th node. We consider that each string appearing in any node at any step has an arbitrarily large number of copies in that node.

$PI, FI \subseteq \mathcal{V}$ are the input permitting/forbidding contexts of the processor, while $PO, FO \subseteq \mathcal{V}$ are the output permitting/forbidding contexts of the processor. These filters can work in four different way as described below:

For two disjoint subsets $P$ and $F$ of an alphabet $\mathcal{V}$ and a word over $\mathcal{V}$, we define the predicates $\phi^{(1)}$ and $\phi^{(2)}$ as follows:

$$\phi^{(1)}(w; P, F) \equiv P \subseteq \text{alph}(w) \land F \cap \text{alph}(w) = \emptyset$$

$$\phi^{(2)}(w; P, F) \equiv \text{alph}(w) \cap P \neq \emptyset \land F \cap \text{alph}(w) = \emptyset.$$  

The construction of these predicates is based on random-context conditions defined by the two sets $P$ (permitting contexts) and $F$ (forbidding contexts). For every language $L \subseteq \mathcal{V}^*$ and $\beta \in \{ (1), (2), (3), (4) \}$, we define:

$$\phi^\beta(L, P, F) = \{ w \in L \mid \phi^\beta(w; P, F) \}.$$  

Finally, $G = ([N_1, N_2, \ldots, N_n], E)$ is an undirected graph called the underlying graph of the network. The edges of $G$, that is the elements of $E$, are given in the form of sets of two nodes.

By a configuration (state) of a NEP as above we mean an $n$-tuple $C = (L_1, L_2, \ldots, L_n)$, with $L_i \subseteq \mathcal{V}^*$ for all $1 \leq i \leq n$. A configuration represents the sets of strings which are present in any node at a given moment. The initial configuration of the network is $C_0 = (A_1, A_2, \ldots, A_n)$. A configuration can change either by an evolutionary step or by a communicating step. When changing by an evolutionary step, each component $L_i$ of the configuration is changed in accordance with the evolutionary rules associated with the node $i$. 
Formally, we say that the configuration \( C_1 = (L_1, L_2, \ldots, L_n) \), directly changes into the configuration \( C_2 = (L'_1, L'_2, \ldots, L'_n) \) by an evolutionary step, written as \( C_1 \Rightarrow C_2 \) if \( L'_i \) is the set of strings obtained by applying the rules of \( R_i \) to the strings in \( L_i \) as follows:

(i) If the same substitution or deletion rule may replace different occurrences of the same symbol within a string, all these occurrences must be replaced within different copies of that string. The result is a multiset in which every string that can be obtained appears in an arbitrarily large number of copies.

(ii) An insertion rule is applied at any position in a string. Again, the result is a multiset in which every string, that can be obtained by application of an insertion rule to an arbitrary position in an existing string, appears in an arbitrarily large number of copies.

(iii) If more than one rule, no matter its type, applies to a string, all of them must be used for different copies of that string.

When changing by a communication step, each node processor \( N_i \) sends all copies of the strings it has which are able to pass its output filter to all the node processors connected to \( N_i \) and receives all copies of the strings sent by any node processor connected with \( N_i \) providing that they can pass its input filter.

Formally, we say that the configuration \( C_1 = (L_1, L_2, \ldots, L_n) \) directly changes into the configuration \( C_2 = (L'_1, L'_2, \ldots, L'_n) \) by a communication step, written as \( C_1 \vdash C_2 \) if

\[
L'_i = L_i \setminus \{w \mid w \in L_i \cap PO_i\} \cup \bigcup_{(N_i,N_j) \in E} \{x \mid x \in L_j \cap PO_j \cap P_i\}
\]

for every \( 1 \leq i \leq n \).

Let \( \Gamma = (V, N_1, N_2, \ldots, N_n) \) be an NEP. By a computation in \( \Gamma \) we mean a sequence of configurations \( C_0, C_1, C_2, \ldots \), where \( C_0 \) is the initial configuration, \( C_{2i} \Rightarrow C_{2i+1} \) and \( C_{2i+1} \vdash C_{2i+2} \) for all \( i \geq 0 \).

If the sequence is finite, we have a finite computation. The result of any finite or infinite computation is a language which is collected in a designated node called the output node of the network. If one considers the output node of the network as being the node \( k \), and if \( C_0, C_1, \ldots \) is a computation, then all strings existing in the node \( k \) at some step \( t \) - the \( k \)-th component of \( C_t \) - belong to the language generated by the network. Let us denote this language by \( L_k(\Gamma) \). The time complexity of computing a finite set of strings \( Z \) is the minimal number of steps \( t \) in a computation \( C_0, C_1, \ldots, C_t \) such that \( Z \) is a subset of the \( k \)-th component of \( C_t \).

A polarized evolutionary processor over \( V \) is a pair \( (M, \alpha) \), where:

- \( M \) is a set of substitution, deletion or insertion rules over the alphabet \( V \).
- Formally: \( (M \subseteq \text{Sub}_V) \) or \( (M \subseteq \text{Del}_V) \) or \( (M \subseteq \text{Sub}_V) \). The set \( M \) represents the set of evolutionary rules of the processor. As one can see, a processor is "specialized" in one evolutionary operation, only.
- \( \alpha \in \{-, 0, +\} \), is the polarization of the node (negatively, neutral or positively charged, respectively).

We denote the set of evolutionary processors over \( V \) by \( EP_V \). Clearly, the evolutionary processor described here is a mathematical concept similar to that of an evolutionary algorithm, both being inspired from the Darwinian evolution. As we mentioned in the Introduction, the rewriting operations we have considered might be interpreted as mutations and the filtering process described above might be viewed as a selection process. Recombination is missing but it was asserted that evolutionary and functional relationships between genes can be captured by taking only local mutations into consideration [Sancoff, 1992].
A network of polarized evolutionary processors (NPEP for short) is a 7-tuple $\Gamma = (V, U, G, R, \varphi, \text{In}, \text{Out})$; where:

- $V$ and $U$ are the input and network alphabet, respectively, $V \subseteq U$;
- $G = (X_G; E_G)$ is an undirected graph without loops with the set of vertices $X_G$ and the set of edges $E_G$. $G$ is called the underlying graph of the network;
- $R: X_G \rightarrow EP_U$ is a mapping which associates with each node $x \in X_G$ the polarized evolutionary processor $R(x) = (M_x, \alpha_x)$;
- $\varphi$ is a valuation of $U^*$ in $\mathbb{Z}$;
- $\text{In}, \text{Out} \in X_G$ are the input and the output node of $\Gamma$, respectively.

A configuration in a NPEP can change either by an evolutionary step or by a communication step as the rest of the models. When changing by an evolutionary step, each component $C(x)$ of the configuration $C$ is changed in accordance with the set of evolutionary rules $M_x$ associated with the node $x$, but when changing by a communication step, each node processor $x \in X_G$ sends out one copy of each string it has, which has a polarity different than that of $x$, to all the node processors connected to $x$ and receives all the strings sent by any node processor connected with $x$ providing that they have with the same polarity as that of $x$. Note that, for simplicity reasons, we prefer to consider that a string migrate to a node with the same polarity and not an opposed one.

Formally, we say that the configuration $C'$ is obtained in one communication step from configuration $C$, written as $C \xleftarrow{c} C'$, iff

$$C'(x) = (C(x) \setminus \{w \in C(x) \mid \varphi \neq \alpha_x \}) \cup \bigcup_{\{x,y\} \in E_G} (C(x) \setminus \{w \in C(y) \mid \alpha_y \neq \varphi = \alpha_x \}),$$

for all $x \in X_G$. Note that strings that have the same polarity as that of the node in which they are remain in that node and can be further modified in the subsequent evolutionary steps, while strings with a different polarity are expelled. Further, each expelled string from a node $x$ that cannot enter any node connected to $x$ (no such node has the same polarity as the string has) is lost.

### Implementation

This simulation is assumed to be a foundation for future additions and adaptations as the findings in this field are moving forward, so the class structure is considered to be lithe by means of the use of interfaces along with abstract classes which gather the common and required features of the formal definition. The relation and dependencies of classes for simulating the NEP model are showed in Figure 1, in a simplified way.

When we are using a web based system we have to consider the specificities for this type of technology where a server receives all upcoming requests and after processing them produces a response. When this processing is known to be a time consuming procedure, an imminent response is preferred rather than waiting for the whole computation to be finished, for that reason we consider running the NEP instance within a thread (ThreadNEP) aside from the request–response process, once the computation is started allowing the access to the NEP when needed.

In this diagram we state the relation among all the involved classes. We thought the main class NEP should be in charge of keeping reference to the rest of the well-known components of a NEP such as the alphabet in a form of a String in which every character is standing for a symbol, the graph, the list of nodes or processors, the stopping conditions and the type of NEP for stating if it is polarized. This class it is also in charge of initiating and controlling the evolutionary and communication processes trough the method go() which is in charge of doing
this rotation of steps in accordance with the established model and controlling with the anyStoppingCondition() the possibility of stopping the processing due to the occurrence of any of the required conditions for stopping the computation. This class also interacts with others devoted to the data management and NEP configuration procedure as well as for retrieving the outcomes of a calculation.

For the Graph class we have an array list of Connection which is a class describing a connection between two nodes by keeping the names of the nodes related in a form of int values, which are also the numbers of the positions of each node in the list of nodes. The method neighbors(int node) of this class was thought to be of use in communication steps for retrieving the list of nodes connected to a given one for next exchange of words among them.

Figure 1. Class diagram of the main design

As we mentioned, the NEP stops when at least one of the stopping condition is met. In this case we have considered covering the most common ones as in jNEP in [Rosal, 2008]. The Figure 1 shows how from an interface it was conceived the general structure of the stopping condition by means of the stop (NEP nep) method allowing future variant to be considered without extended variation since each of the four are already in the implementing classes (StoppingConditionConsecutiveConfiguration, StoppingConditionWordsDisappear, StoppingConditionNonEmpty, StoppingConditionStep) of interface IStoppingCondition share the same method but differing in theirs attributes. Explaining each one of them we say that for the StoppingConditionConsecutiveConfiguration to succeed stopping the computation if two consecutive identical configurations are found once communication and evolutionary steps were
performed. For the \texttt{StoppingConditionWordsDisappear} to trigger the stop if none of the words listed are in the NEP. The \texttt{StoppingConditionNonEmpty} if one of the nodes is non-empty and the \texttt{StoppingConditionStep} for stopping after a given amount of steps.

The processors are other key components of a NEP simulation, in this they are referred as nodes. The Node class which has a \texttt{polarity} attribute useful for the polarization process and also having a \texttt{MultiSet} reference, standing for the group of words of the processor treated as an \texttt{ArrayList<Word>} and implementing a group of methods useful for the filtering and rules application processes.

In the nodes we have a list of rules defined by the \texttt{IRule} interface and instantiated buy a group of the classes: InsertionRule, DeletionRule, SubstitutionRule the ones are meant to cover the basic model of NEP, implementing the \texttt{applyRule(String word)} method of the interface and inheriting from the Rule class, not considered in the class diagram for space reasons. The common attributes come from Rule as symbol, to represent the symbol to apply the rule to, coming as a String but so far considering the only character it carries and the attribute how, also a String referring the way it has to be done as in the position the rule has to be used, having one of this values: \texttt{left}, \texttt{right}, \texttt{any}. This also reworks the basic model which was conceived for applying rules at the end of the word.

Nodes have two filters as attributes, the \texttt{inputfilter} and the \texttt{outputfilter} which are instantiated from one of the four filtering classes (\texttt{Filter1}, \texttt{Filter2}, \texttt{Filter3}, \texttt{Filter4}) according to the level of strength in the filtering processes described in [Martín-Vide, 2003], each one implementing the \texttt{IFilter} interface where the \texttt{applyFilter()} returns a list of words able to pass the filter and the \texttt{passFilter()} for considering a single word.

\texttt{EvolutionaryStep} is the class conceived to manage the list of nodes for the purpose of performing an evolutionary step; for doing that and by means of generating a new thread by each node in every step. For that, it requires the \texttt{ThreadNode} class which uses a node reference to access the node multiset and rules. The \texttt{run()} method in every thread applies randomly the rules to every word and every copy till no more can be applied. Once the evolutionary step is finished the NEP commands to the method \texttt{apply(ArrayList<Node> nodes, Graph graph)} of the \texttt{CommunicatingStep} class to proceed with the exchange of words using the defined filters of each node.

The need of a way for pleasantly interacting and storing the different designs of NEP is something considered in this implementation. The use of a web based platform fits for the purpose of availability and manageability. Some previous application for these models do not present a solution for this matter but for only for storing and reading from a configuration file which the user has to learn how to create. In the Figure 2 we show the interaction between components as in a MVC pattern.

\begin{figure}[h]
\centering
\includegraphics[width=\textwidth]{mvc.png}
\caption{MVC design pattern.}
\end{figure}
The relationship between classes is centered in the controllers dealing with the logic of the program having one by each use case, loading, configuring and running, implemented by the servlets LoadNEPServlet, ConfigurationServlet, and RunServlet illustrated in Figure 3.

Once the initial page starts it is necessary to upload the file containing the NEP description, specified in a json syntax, to the NEP instance by means of the getSavedConfiguration(String path) method of the PersistentConfiguration class contained in the data access package, accessible through the Load NEP link placed in the menu at the left as shown in Figure 4 which allows us to locate and select the desired configuration.

The configuration page is responsible for the main interaction with the user allowing the creation and modification of a current NEP. The use of the UserNep class is given as a translation mechanism between the form of writing in the visual components and the NEP object oriented structure. For example in Figure 5 for defining the graph, a structure in the way of tuples of nodes numbers associated with a colon and delimited through brackets as follows: (0,1)(1,2) (2,0). For that purpose the readGraphString(String sgraph) is in charge of the translation of a string representation of the graph to a Graph class form, in the opposite direction the writeGraph(NEP nep) method is responsible of putting in a string form the Graph content required for visualizing it in the updateConfiguration page.

In this view the colon is used for separating the individual elements as words in the multiset, also the symbolization -> for describing the rules having consequent, not for the deletion or insertion rules which only
requires the one different from the empty symbol. The filters’ section is shown only if required, for instance when the NEP is not polarized.

The Node panel also in Figure 5 allows us to move through the different nodes using the <<<<<Previous Node<<<<<, and >>>>>Next Node >>>>> buttons as well as going directly to the desired one if the configuration is too long.
When running the NEP the `run()` procedure of `ThreadNEP` instance is activated and the result of the desired node is shown automatically or by demand as it is illustrated in Figure 6.

**Figure 6.** Running page

## Conclusion

In this paper we have described the design and implementation of an abstract computer devise called NEP, aiming to achieve a solution based in a Web development for gaining accessibility and fitting the most common variants of the models. The use of a graphic user interface is also one of the first attempts of this type of simulations allowing a fast and pleasant configuration of the NEP.

For next improvements we are evaluating the use of a database for storing a group of different results of the same problem in order to ease the analysis of the outcomes, although it would also improve the configuration proces.

This work act as an instrument for future analysis of the different variants the NEP family as it will be submitted to forthcoming developments in order complete a better and more complete solution.
